ABSTRACT

Nanostructured TiO_2 and $Mo-TiO_2$ were prepared by a sol-gel method at ambient temperature, followed by modification using non-thermal plasma. The as-prepared photocatalysts were characterized by XRD, TEM, and UV-Vis DRS, as well as BET and XPS analyses. XRD results indicated that the TiO_2 and $Mo-TiO_2$ lattice structures before and after plasma treatment are similar except for the crystal size. TEM images indicated that plasma-treated catalysts exhibit better dispersibility. The BET analysis of the plasma-treated catalysts indicated a larger specific surface area and pore diameter. XPS results confirmed that Mo is doped into the TiO_2 lattice, and the characteristic peaks shift to higher energy after plasma treatment. UV-Vis DRS analysis of the doped and plasma-treated TiO_2 photocatalytic materials indicated a red-shift of absorption to the visible region. Toluene, which is a typical volatile organic compound (VOC), was chosen as a model air pollutant. The photocatalytic activities of prepared photocatalysts were investigated in a gas-solid photoreactor for the decomposition of gaseous toluene. Results indicated that materials modified by non-thermal plasma exhibit higher photocatalytic activities.

Keywords: Non-thermal plasma; Photocatalysis; Volatile organic compound; Sol-gel method

INTRODUCTION

The modernization of economy and industry has led to a major issue of air pollution in several areas [1]. Volatile organic compounds (VOCs) are regarded as one of the most significant air pollutants caused by human activity [2]. VOCs include hazardous substances, which are predominantly responsible for the formation of smog and ozone precursors. In addition, these compounds are suspected to be pathogenic factors of cancer, which can render temporary or permanent toxic effects on the hematological, respiratory, and liver systems, as well as other organs in the human body, and cause severe threat to the human living environment and even our survival [3]. The main components of VOCs include benzene homologs, where toluene is a typical compound [4]. With increasing concerns on the harm of toluene to human in the air, especially the indoor atmosphere, the treatment of toluene is attracting immense interest. Several studies have been conducted to find an efficient, convenient, and low-cost photocatalyst for the decomposition of gaseous toluene in air at room temperature [5-8].

From an in-depth study using TiO_2 semiconductors reported previously, the absorption wavelength of TiO_2 shifts from the ultraviolet to the visible-light region [9], demonstrating potential in photocatalysis. Studies reported in related fields have explored different methods for decreasing the band gap of TiO_2 so as to observe an optical response in the visible range [10-13]. To extend the absorption of TiO_2 in the visible range so as to completely exploit solar energy, doping using impurities is the typical modification method for sensitizing the property of TiO_2 . A number of studies have demonstrated that the doping of TiO_2 improves its absorption property to visible light [14-16]. However, the enhancement of visible-light absorption has been reported to not sufficiently increase the catalytic activity [17,18]. Plasma is gas in the ionized state, which contains a large number of electrons, ions, neutral atoms, excited atoms, photons, and free radicals, and of these components, the electronic charge is numerically equal to the positive charge. During the doping of TiO_2 by the traditional sol–gel method, contaminants can be introduced into the surface or interstitial sites of the TiO_2 lattice, which can act as defects and recombination centers, lead to the rapid recombination of photoinduced electrons and holes, and decrease photon efficiency. To prevent the inactivation of photocatalysts, some new techniques, e.g., plasma treatment as well as ultrasound and microwave irradiation has been reported, with constructive results [19,20]. Non-thermal plasma treatment is satisfactory because it is a high-energy, low-cost, energy-efficient application [21,22].

In this study, TiO_2 and Mo- TiO_2 photocatalysts were prepared by a conventional sol-gel method, followed by moisture removal and calcination for crystallization. Next, the prepared samples were treated by non-thermal plasma for a specific time. The plasma-treated catalysts exhibited better photocatalytic activity for the decomposition of gaseous toluene.

EXPERIMENTAL SECTION

Preparation of TiO₂

First, 10 mL of butyl titanate and 2 mL of acetylacetonate (ACAC) were added into 50 mL of ethanol to prepare a mixed solution. Second, 2 g of cetyltrimethylammonium bromide (CTAB) and 3 g of glucose ($C_6H_{12}O_6$) were stirred at room temperature for 30 min to obtain solution "A." Third, 2 mL of deionized water was added into 25 mL of ethanol, and the pH was adjusted to 4–6 by nitric acid (65% wt), followed by thorough stirring to obtain solution "B." Next, solution "B" was added dropwise into solution "A" to ensure slow hydrolysis for butyl titanate. The mixture was stirred for another hour, affording a light-yellow uniform transparent TiO₂ sol after drop ended. Next, the sol was aged at room temperature for 24 h, affording a TiO₂ wet gel. Finally, the gel was completely dried in a vacuum oven for 12 h at 80°C, affording a xerogel, followed by the grinding of samples and sieving into powders. These powders were calcined for 5 h at 500°C, affording anatase TiO₂.

Preparation of Mo-TiO₂

Mo-TiO₂ nanoparticles were prepared by the addition of ammonium molybdate ((NH_4)₆Mo₇O₂₄·4H₂O, A.R.) into solution "B" as the Mo precursor. All remaining steps were the same as those utilized for the preparation of pure TiO₂.

Non-thermal Plasma Treatment

The prepared TiO_2 and $Mo-TiO_2$ samples were modified using non-thermal plasma for 30 min. Ar was used for the glow discharge, with a treatment pressure of 30–40 Pa and a power of 36 W.

Catalyst Characterization

The crystalline phase of the samples was investigated by X-ray diffraction (XRD) using a DX-2700 diffractometer utilizing Cu K α radiation ($\lambda = 0.15406$ nm). The morphology of the catalysts was observed by transmission electron microscopy (TEM) using a CM120 system (Philips, The Netherlands). Specific surface areas were determined by BET analysis using an ASAP 2020M system (Micromeritics, USA) at 77 K. X-ray photoelectron spectroscopy (XPS) was employed to investigate the chemical composition of the samples. UV–Vis diffuse reflectance spectra (UV–Vis DRS) were recorded on a UV-2600 (Shimadzu, Japan) system. The photoabsorption property of the powders was recorded using BaSO₄ tablet as the reference.

Photocatalytic Degradation of Toluene

Toluene was chosen as a typical VOC in air to evaluate the photocatalytic performance of the samples. The photocatalysts were uniformly tiled in a rectangular quartz reactor under light irradiation. Simulated sunlight was generated using a high-pressure xenon lamp (HPXL, 500 W). The light source and reactor were cooled using circulating water ($50 \pm 5^{\circ}$ C). The toluene concentration was analyzed by a GC 6890N system (Agilent, USA) with an HP-5 column using N₂ as the carrier and H₂ for burning.

RESULTS AND DISCUSSION

Catalyst Characterization

XRD and BET analysis:

Figure 1 shows the XRD spectra of the as-prepared photocatalysts. Similar diffraction curves were observed for all samples. Characteristic peaks were observed at 25.3°, 37.8°, 48.2°, 54.2°, 55.2°, 62.7°, 68.6°, 70.5°, and 75.1°, corresponding to the (101), (004), (200), (105), (211), (204), (116), (220), and (215) crystalline planes of the anatase TiO₂ surface, respectively (JCPDS card No. 21-1272) [23]. A diffraction peak corresponding to the

Mo phase was not observed, caused by the similar ionic radii of Mo and Ti; hence, Mo can be easily substituted into the TiO₂ lattice without any change in the TiO₂ crystal phase. After doping and plasma treatment, the peaks corresponding to the catalysts were weaker and wider as compared with those corresponding to pure TiO₂. Particularly, after plasma treatment, Mo-TiO₂ exhibited the widest, weakest peaks for anatase, indicating higher lattice disorder and a smaller crystal size. The Scherrer equation and BET analysis were utilized to calculate the physiochemical properties of the samples. Table 1 shows the results. As can be observed from Table 1, the crystal size decreased after plasma treatment. The specific surface area, total pore volume, and average pore diameter of plasma-treated catalysts increased. After plasma treatment, the pollutants attached to the catalyst surface and present in the lattice gap were removed, resulting in better texture.

Figure 1: XRD patterns of the catalysts

Table 1: Physiochemical properties of the catalysts

Sample	Crystal size (nm)	Specific surface area (m ² /g)	Total pore volume (cm ³ /g)	Average pore diameter (Å)
TiO ₂	23	20.1	0.21	106.1
Plasma TiO ₂	18.2	30.1	0.25	205.1
Mo-TiO ₂	17.5	29.6	0.17	218.1
Plasma Mo-TiO ₂	16.8	38.7	0.19	276.3

XPS analysis:

Figure 2: XPS spectra of a: Ti 2p; b: Mo 3d peaks of the catalysts

Figure 2 shows the XPS spectra of Ti 2p and Mo 3d peaks in the prepared catalysts. The electron binding energy was calibrated using C1s (284.6 eV) as the reference. As can be observed from the graph, the characteristic peaks observed at around 459 eV and 464.8 eV were typical of Ti $2P_{3/2}$ and Ti $2P_{1/2}$ for the Ti ion, respectively. Binding energies of 232.5 eV and 235.9 eV corresponded to the Mo $3d_{5/2}$ and Mo $3d_{3/2}$ peaks of the Mo ion, respectively [24]. The binding energy of the peaks shifted to high electric potentials, with the peak intensity increasing with plasma treatment, indicating that the ionic strength is enhanced after plasma treatment, possibly caused by the generation of excited particles in the plasma that remove the contaminating electrons and organics. Hence, the number of active sites increases and catalyst performance is promoted.

TEM morphology:

Figure 3: TEM images of the a: TiO₂; b: plasma TiO₂; c: Mo-TiO₂; d: plasma Mo-TiO₂ catalysts

Figure 3 shows the TEM images of the catalysts. Before plasma treatment, the catalysts exhibited aggregated structures with layered and massive blocks, and large gaps and spaces were observed between the blocks. However, with plasma treatment, the catalysts exhibited a uniformly dispersed porous structure, and large blocks transformed into small particles, possibly caused by the cleaning and scattering effect of high-energy molecules in plasma; these molecules were beneficial for improving the photocatalytic efficiency.

Figure 4: a: UV-vis DRS spectra and; b: Tauc plot of the catalysts

To investigate the optical absorption property of the catalysts, UV-Vis DRS measurements of the samples were conducted. Figure 4a shows the absorption curve spectra of the catalyst samples. The absorption band corresponding to plasma TiO₂ and Mo-TiO₂ shifted to a higher absorption wavelength of visible light as compared with that of the untreated catalysts. Generally, the band gap of semiconductors is related to the absorption wavelength, and the Tauc plot [25] curve of the $(\alpha hv)^{1/2}$ – hv can be obtained by the calculation of the optical absorption data using the Kubelka-Munk equation [26]. As can be observed from the Tauc plot, the band gap of the catalysts was inversely proportional to the absorption wavelength: catalysts with a narrow band gap were excited by visible light. As a result, the band gap of the catalysts subjected to plasma treatment is less than those of untreated TiO_2 and Mo-TiO₂. Table 2 summarizes the absorption edge and band gap of the catalysts. Particularly, plasma Mo-TiO₂ exhibited a band gap energy of 2.94 eV, which was less than those of other catalysts. Previous studies have confirmed that doping with Mo possibly enhances the visible absorption property of TiO₂ [27]. When the catalysts are exposed to the plasma atmosphere, several excited particles impinge on their surfaces. As mentioned above, these energetic particles are capable of cleaning the catalyst surface or gaps and breaking massive blocks into small particles. Hence, the number of free radicals on the catalyst surface increases, consequently promoting the optical absorption property of visible light. With the enhancement of the visible absorption, the photoelectric quantum efficiency of TiO₂ can be enhanced because of the high generation of photoinduced electrons and holes in the photocatalytic process.

Table 2: Absorption edge and band gap of the catalysts

	TiO ₂	Mo-TiO ₂	Plasma TiO ₂	Plasma Mo-TiO ₂
Absorption edge (nm)	398.7	407.9	416.1	421.8
Band gap (eV)	3.11	3.04	2.98	2.94

Comparative Study of Photocatalytic Activity of the Catalysts

Figure 4: a: Variation of the decomposition efficiency of toluene over the catalysts under visible-light irradiation; b: Variation of $\ln(C_0/C)$ of toluene over the catalysts under visible-light irradiation

Figure 4a shows the photocatalytic decomposition efficiency of gaseous toluene over different catalysts (i.e., pure TiO₂, Mo-TiO₂, plasma TiO₂, and plasma Mo-TiO₂) under visible-light irradiation. Simulated toluene gas was generated from a high-pressure cylinder of high-purity air injected with toluene vapor. The flow rate was 100 mL/min, the toluene initial concentration was 100 ppm, and the relative humidity was regulated at $35 \pm 5\%$ by water evaporation. As can be observed from the figure, the toluene decomposition efficiency for all samples increased over the irradiation time and was gradually maintained steady after 80 min. A plateau was observed from 20 min to 30 min, possibly associated with the desorption of the toluene adsorbed on the catalysts with increasing temperature under irradiation. Different catalysts exhibited different photocatalytic activities. In particular, the toluene decomposition efficiencies for all catalysts under visible light followed the order of plasma Mo-TiO₂ > plasma TiO₂ > Mo-TiO₂ > TiO₂. For plasma Mo-TiO₂, the toluene decomposition efficiency rapidly increased over the irradiation time and attained the highest stable value at around 80%. Previous studies have reported that the photocatalytic degradation of VOCs is regarded as the pseudo first-order reaction [28,29]. The kinetic rate of the process can be expressed as the Langmuir–Hinshelwood model:

$$\ln (C_0 / C) = kt + b$$

Here, C_0 is the initial toluene concentration at t = 0, *C* is the residual toluene concentration at *t*, and *k* is the rate constant of the reaction. Figure 4b shows the curve of $\ln(C_0/C)$ versus the irradiation time of toluene over the catalysts with visible-light irradiation. The photocatalytic degradation rate of toluene can be expressed by the slope of the straight line. As can be observed from the figure, the reaction rate constants for TiO₂, Mo-TiO₂, plasma TiO₂, and plasma Mo-TiO₂ were 0.0063, 0.0076, 0.0109, and 0.0190, respectively. The photocatalytic activity of plasma Mo-TiO₂ was clearly greater than those of other samples, which is approximately three times that of TiO₂. The high photocatalytic activity for plasma Mo-TiO₂ is possibly caused by synergistic effects of Mo doping and non-thermal plasma. On the one hand, with the doping of Mo into the TiO₂ lattice, mid band gaps between the valence and conduction bands are possibly generated, the band gap width of samples shifted to the visible region; hence, the light-absorption range by samples is effectively enhanced, which promotes the photoinduced quantum efficiency of solar light illumination. On the other hand, the special interface in the catalyst prepared by plasma not only can improve the physiochemical property of Mo ions and the TiO₂ semiconductor but also increase the transfer and resolution efficiencies of the photoinduced electrons and holes. In addition, plasma-treated catalysts exhibited better dispersibility, stability, and optical absorption property; thus, photocatalytic efficiency is significantly promoted.

Because of the complexity of plasma, the reaction mechanism for the plasma treatment of catalysts is still not clear. From characterization data, plasma catalysts exhibit a small crystal size, large specific surface area, and agglomeration after calcination. Hence, when the plasma is in complete contact with the catalysts, the excited particles in plasma can be attached on the catalyst surface and form a plasma layer. The internal electric field will positively affect the catalysts and promote the efficiency of photon collection. In addition, the plasma layer on the nanoparticles can repel each other and improve the dispersion of catalysts, thereby promoting the photocatalytic efficiency.

CONCLUSION

Nanostructured-plasma Mo-doped TiO_2 photocatalysts were synthesized by the sol-gel method and non-thermal plasma treatment. Furthermore, the prepared catalysts were applied to the decomposition of toluene under visible light. The photocatalytic activity of plasma Mo-TiO₂ was greater than those of TiO₂, Mo-TiO₂, and plasma TiO₂. Characterization results indicated that the properties (crystal size, specific surface area, dispersibility, and optical absorption) of plasma Mo-TiO₂ are superior than those of other catalysts, which are beneficial for visible-light photocatalysis. The high photocatalytic efficiency of plasma Mo-TiO₂ was related to the synergism of Mo doping and plasma treatment. Plasma technology can obviously improve the physiochemical properties of the catalysts, as well as demonstrates promise for applications in solving environmental problems.
